ABSTRACT
We present observations of the CO(1-0) emission in the central 750 pc (10 arcsec) of the counter-rotating disc galaxy NGC 4550, obtained at the Institut de Radioastronomie Millimétrique (IRAM) Plateau de Bure Interferometer. Very little molecular gas is detected, only $1 \times 10^7 \, M_\odot$, and its distribution is lopsided, with twice as much molecular gas observed at positive relative velocities than at negative relative velocities. The velocity gradient in the CO(1-0) emission shows that the molecular gas rotates like the thicker of the two stellar discs, which is an unexpected alignment of rotations if the thinner disc was formed by a major gas accretion event. However, a simulation shows that the gas rotating like the thicker disc naturally results from the coplanar merger of two counter-rotating disc galaxies, demonstrating the feasibility of this scenario for the formation of NGC 4550. We investigate various star formation tracers to determine whether the molecular gas in NGC 4550 is currently forming stars. Ultraviolet (UV) imaging data and optical absorption line strengths both suggest a recent star formation episode; the best-fitting two-population model to the UV-optical colours yields a mass of young stars of $5.9 \times 10^7 \, M_\odot$ with an age of 280 Myr. The best information on the current star formation rate is a far-infrared-based upper limit of only $0.02 \, M_\odot \, yr^{-1}$. We are thus witnessing NGC 4550 either in a dip within a bursty star formation period or during a more continuous low-level star formation episode.

Key words: galaxies: elliptical and lenticular, cD – galaxies: individual: NGC 4550 – galaxies: ISM – galaxies: kinematics and dynamics – galaxies: stellar content – ultraviolet: galaxies.

1 INTRODUCTION
Deciphering star formation histories of early-type galaxies is important for understanding their formation and evolution. While early-type galaxies were traditionally considered to be simple single stellar populations, it is now clear that their star formation histories must be more complicated. Both absorption line strengths (e.g. Trager et al. 2000) and UV-optical colours (Yi et al. 2005; Kaviraj et al. 2007) indicate that a significant portion of early-type galaxies have recently formed stars ($\approx 30$ per cent from the UV-optical colours). Reassuringly, molecular gas, the raw material for star formation, is also found in early-type galaxies (Henkel & Wiklind 1997). Two recent surveys give detection rates of 28 per cent for E/S0s in the Spectrographic Areal Unit for Research on Optical Nebulae (SAURON) sample (Combes, Young & Bureau 2007) and 78 per cent for S0s in a volume-limited sample (Sage & Welch 2006).

NGC 4550 is an unusual galaxy (see Table 1), containing two coplanar counter-rotating stellar exponential discs with nearly identical scalelengths (Rubin, Graham & Kenney 1992; Rix et al. 1992). However, integral field unit data show that one disc is thicker and has a higher velocity dispersion than the other (Kenney, Faundez & Murphy 2000; Emsellem et al. 2004). The Schwarzschild modelling by Cappellari et al. (2007) confirms the difference in scaleheights and additionally shows that the two discs have equal mass within the SAURON field-of-view. The presence of these two discs with different scaleheights may cause the failure of some bulge–disc decompositions. Rix et al. (1992) find a bulge-to-disc ratio of only 0.19, while Scorza et al. (1998) report a ratio of 5. The Sérsic fit of Ferrarese et al. (2006) gives a best-fitting Sérsic shape parameter of 1.7, demonstrating that the surface brightness profile is not
molecular gas in NGC 4550 alerts us to another early-type galaxy with ongoing star formation, or whether the molecular gas instead appears to be stable.

2 PLATEAU DE BURE OBSERVATIONS

2.1 Observations

NGC 4550 was observed in the $^{12}$CO(1-0) line with the IRAM Plateau de Bure Interferometer (PdBI) on 2007 August 10. The observations were taken in the D configuration with five antennas and used the new generation dual-polarization receivers at 3 mm.

The spectral correlators were centred at 115.12 GHz, the transition frequency of CO(1-0) roughly corrected for the heliocentric velocity of NGC 4550. The correlator configuration used four 320 MHz wide (834 km s$^{-1}$) units with a frequency resolution of 2.5 MHz (6.6 km s$^{-1}$), covering a total usable bandwidth of 950 MHz (2475 km s$^{-1}$). The correlator was regularly calibrated by a noise source inserted in the internal frequency (IF) system.

We obtained visibilities with a series of thirty 45 s integrations on source, followed by three 45 s phase and amplitude calibrations on each of the two phase calibrators (see Table 2). To flux calibrate, we set the flux density of 3C273 to the expected value (15 Jy), and then checked that the fluxes found for the other flux calibrators were reasonable. The uncertainty in our flux calibration is ±20 per cent.

The data were reduced with the Grenoble Image and Line Data Analysis System (GILDAS) software packages CLIC and MAPPING (Guilloteau & Lucas 2000). We calibrated the data using the standard pipeline in CLIC. After calibration, we used MAPPING to create data cubes centred at 115.104 GHz (corrected more precisely for a systemic velocity of 435 km s$^{-1}$) with velocity planes separated by 20 km s$^{-1}$. Natural weighting was used. The primary beam size is 44 arcsec for CO(1-0), and we chose the spatial dimensions of the data cube to be about twice the diameter of the primary beam, 90×90 arcsec$^2$. The synthesized beam is 4.7×4.0 arcsec$^2$, so we choose spatial pixels of 1×1 arcsec$^2$. Continuum subtraction was unnecessary (see below). The dirty beam has small side lobes that necessitated cleaning the data cube. The cleaning was done using the Högbohm method (Högbohm 1974); we stopped cleaning in each velocity plane after the brightest residual pixel had a value lower than the rms noise of the uncleaned data cube.

To constrain the continuum emission, we selected frequencies at least 40 km s$^{-1}$ away from the lowest and highest velocity channels with any line emission in the cleaned data cube (~80 and 80 km s$^{-1}$, respectively). The very edges of the bandwidth were also avoided, resulting in a 683 MHz wide continuum window. We mapped these data with the same spatial parameters as the line data. No emission could be seen in the map with a rms noise of 0.54 mJy beam$^{-1}$, giving a 3σ upper limit of 1.62 mJy assuming a point source.

2.2 Results

The channel maps (Fig. 1) show CO(1-0) emission around the galaxy centre. The emission is just over the 3σ level, with stronger...
emission in the 20, 40 and 60 km s\(^{-1}\) channels. The channel velocity values are all given with respect to systemic velocity. In the channel maps, a mild velocity gradient is observed, with more of the emission at positive relative velocities to the north of the galaxy centre and more of the emission at negative relative velocities to the south. The 60 km s\(^{-1}\) channel is an exception with a peak slightly south of the galaxy centre, although the emission clearly also extends to the north. To pick up more extended emission, we created an integrated intensity map and a mean velocity field map (Fig. 2) using the smoothed-mask method. To make these maps, we first created a smoothed cube by smoothing with a 2D circular Gaussian spatially (full width at half-maximum of 4 arcsec or about one synthesized beam width). Then, we hanning smoothed by 3 channels in velocity. The moments were computed only using pixels in the original cube that corresponded to pixels above 3\(\sigma\) in the smoothed cube.

The integrated intensity map shows that the emission is limited to the central 750 pc (10 arcsec) in diameter and is slightly stronger in the north. The mean velocity map shows a north–south gradient, as expected from the shift observed in the channel maps. Assuming the velocity gradient indicates rotation around the centre of the galaxy, the molecular gas rotates like the observed ionized gas and the thicker disc. Spatially integrating the entire data cube over the region with observed emission results in the spectrum shown in Fig. 3. This spectrum shows that the emission is present in all channels between \(-80\) and \(80\) km s\(^{-1}\), but is strictly limited to these channels.

While the lopsidedness of the CO emission was discovered by Wiklind & Henkel (2001), the degree of asymmetry was exaggerated due to their use of an incorrect systemic velocity. The systemic velocity listed in NASA Extragalactic Data base (NED) for NGC 4550 and that used by Wiklind & Henkel (2001) is \(381 \pm 9\) km s\(^{-1}\). This value is based on the \(\text{H} \i\) measurement of Peterson (1979). More recent and more sensitive \(\text{H} \i\) observations have not
detected H\textsc{i} (Duprie & Schneider 1996; Oosterloo et al., in preparation), making the Peterson (1979) value very questionable. In addition, recent absorption line studies seem to be converging to a value of around 435 km s$^{-1}$ (Rubin, Kenney & Young 1997) find 434 km s$^{-1}$, Falco et al. (1999) list 458 $\pm$ 41 km s$^{-1}$, Wegner et al. (2003) find 437 $\pm$ 15 km s$^{-1}$ and the velocity in the central pixel of the SAURON velocity map is 435 km s$^{-1}$. We have adopted this value for our work. Then, the flux from positive relative velocities is 1.64 Jy km s$^{-1}$, around twice as much as the flux from negative relative velocities of 0.91 Jy km s$^{-1}$. The ionized gas does not show the same bias as the molecular gas, with fairly symmetric emission in both space and velocity. In addition, the extent of the ionized gas is much greater than that observed in the molecular gas (see Fig. 4). As shown in Wiklind & Henkel (2001), however, the dust favours the north, in agreement with the molecular gas bias.

Integrating the spectrum over the velocity range observed, i.e. from $-80$ to 80 km s$^{-1}$, we obtain a total CO flux of 2.77 Jy km s$^{-1}$. The total flux is used to compute the total molecular hydrogen mass using the formula $M(\text{H}_2) = (1.22 \times 10^4 M_\odot D^2/S_{CO})$, where $D$ is the distance measured in Mpc and $S_{CO}$ is the total CO(1-0) flux. This formula comes from using the standard CO to H$_2$ conversion ratio $N(\text{H}_2)/I(\text{CO}) = 3 \times 10^{20}$ cm$^{-2}$, where $N(\text{H}_2)$ is the column density of H$_2$ and $I(\text{CO})$ is the CO(1-0) intensity in K km s$^{-1}$. We note that the actual conversion ratio for NGC 4550 is unknown and can be expected to vary by a factor of at least two (e.g. Leroy et al. 2007). However, using the specified conversion ratio, the total H$_2$ mass detected by our interferometric observations is $8.1 \times 10^5 M_\odot$.

Using the same value of $N(\text{H}_2)/I(\text{CO})$ and the same distance to NGC 4550, the single-dispersion measurement of Wiklind & Henkel (2001) gives a molecular mass of $1.4 \times 10^7 M_\odot$, slightly less than twice the value we obtain. However, they integrate over a much larger velocity range (225 to 535 km s$^{-1}$), likely including much noise as positive emission (our velocity range is only 355 to 515 km s$^{-1}$). Over a similar velocity range, our estimates for the molecular mass in NGC 4550 would be in suitable agreement, considering calibration uncertainties ($\approx 20$ per cent). Reflecting the calibration uncertainty and the much larger uncertainty in the conversion ratio, we report the molecular mass in NGC 4550 as $1 \times 10^7 M_\odot$, which is the value we will use for the rest of the paper.

### 3 Numerical Simulation

While both the gas accretion and coplanar major merger scenarios seem to be able to produce at least the general properties of the two stellar discs in NGC 4550, we would also like to know how the gas in this galaxy came to rotate like the thicker disc. Gas rotating like the thick disc is actually in disagreement with the predictions of the gas accretion scenario, in which the thin disc is formed from the acquired cold gas (Kenney et al. 2000). Any remaining gas would then be expected to rotate like the thin disc. To see what the merger scenario predicts for the gas, we have performed a numerical simulation, described below.

#### 3.1 Method and initial conditions

Our merger simulation for NGC 4550 has been run with the same tree-sph technique as described in Di Matteo et al. (2007). The two merging galaxies are initially of the same type (Sb) and mass (each has a total mass of $2.4 \times 10^{11} M_\odot$ including dark matter). The bulges and haloes are modelled as Plummer spheres, of masses 1.15 and $17.25 \times 10^{10} M_\odot$, and characteristic radii 1 and 12 kpc, respectively. The stellar discs have masses of $4.6 \times 10^{10} M_\odot$ and radial scalelengths of 5 kpc. The gas to stellar disc mass ratio is 0.2.

The initial separation between the two galaxies is 100 kpc. We choose an orbit for the galaxies such that they would have a parabolic encounter if they were both point masses. If the galaxies followed the parabolic orbit, the first pericentre would be 8 kpc and their relative velocity at this point would be 707 km s$^{-1}$. Of course, the model galaxies do not follow this Keplerian orbit. Instead, given the strong dynamical friction, merging occurs rapidly. The orbital angular momentum is initially oriented in the positive $z$-axis as is the spin of one of the two galaxies (hereafter called the prograde galaxy). The other galaxy has negative spin (and will be called the retrograde galaxy).

The total number of particles is 240 000, with 120 000 in each galaxy, divided between 40 000 in the gas, 40 000 in the stars and 40 000 in the dark matter halo. We use the Schmidt law and hybrid particles to take star formation into account as in Di Matteo et al. (2007). In the following, when we refer to the ‘gas component’, this means the sum of the gas particles and the very young stars formed since the merger.

#### 3.2 Analysis and results

Fig. 5 shows the gas and stellar particles for six snapshots from 250 to 1500 Myr. The simulation was run until $T = 4000$ Myr (with a time-step of 0.5 Myr), but the evolution after 1500 Myr is only secular relaxation of the merger remnant.

With the spin of one galaxy aligned with the orbital motion and the spin of the other anti-aligned, the interaction is strongly asymmetric despite the equal mass of the galaxies. The prograde galaxy develops long tidal tails, while the retrograde is less heavily influenced by the interaction. As the merger evolves, the central regions become dominated by the stars from the retrograde galaxy as it remains more compact. However, the gas behaves differently due to its collisional nature. While two counter-rotating systems of
Molecular gas and star formation in NGC 4550

Figure 5. Particle plots (x-y projection) of six snapshots of the simulation: the face-on views of the gas (left-hand side; blue) and stars (right-hand side; red) are plotted for each epoch, $T = 250$ to $1500$ Myr in steps of $250$ Myr. The relative orbital motion is counter-clockwise in this picture, where the prograde galaxy is labelled ‘P’ and the retrograde one ‘R’. The merger is complete at the third snapshot ($T = 750$ Myr), with some gaseous tidal dwarfs remaining thereafter. All boxes are 80 kpc wide.

Figure 6. The edge-on ($x$-$z$) stellar density (left-hand side), gas density contours (middle) and gas velocity field (right-hand side) are plotted for two times after the merger, $T = 1000$ and $1250$ Myr. It is easy to see that the settling of the gas occurs during this epoch: the gas density contours flatten and the gas velocity field becomes regular. The boxes are all 10 kpc wide, the wedges at the right of the velocity maps indicate the amplitude of the projected velocities in unit of $100$ km s$^{-1}$. All later snapshots are similar to the $T = 1250$ Myr one, with a regular rotation velocity map for the gas.

stars can coexist, one of the gas systems must dominate. Initially, the gas from the prograde galaxy expands in tidal tails and even tidal dwarfs. However, this gas then falls back and settles in the disc of the merger remnant due to its dissipative nature. Since the orbital angular momentum is positive, the prograde gas increases its angular momentum and the retrograde gas loses some of its angular momentum in the encounter. This results in the gas rotating with positive angular momentum after the gas from the two discs has interacted and fully settled down.

Fig. 6 displays both the edge-on gas density and velocity map for two time-steps: it explicitly reveals how the gas settles into a thin disc while re-ordering its kinematics to prograde rotation. More quantitatively, Fig. 7 shows the global rotation curves along an edge-on projection, splitting the rotational profiles according...
to the various components, the gas and stars in the two galaxies. The rotation curves make it very clear that the stars in the retrograde galaxy retain their direction of rotation, dominating the total rotation curve in the centre of the galaxy. The stars from the prograde galaxy show a lower amplitude of rotation, as they have been strongly heated in the encounter. The merger has thus created a disc galaxy with one dynamically hotter disc of stars, one dynamically cooler counter-rotating disc of stars and a gaseous component rotating like the thick disc. As the alignment of the orbital angular momentum with the prograde galaxy causes both the heating of this galaxy and the settling of the gas into prograde rotation, we predict that in such systems the gas will always be in corotation with the most perturbed stellar system, i.e. with the hotter disc. NGC 4550 clearly exhibits this phenomenon with both the molecular and ionized gas rotating like the thicker stellar disc.

However, in the present simulation with perfectly coplanar galaxies, we note that there is not much heating in the perpendicular direction. The thickness of the stars with positive angular momentum (those that would observationally be considered in the prograde disc) is comparable to the thickness of the stars with negative angular momentum. While the lack of a bona fide thicker disc limits the direct comparison to NGC 4550, we expect more resonant heating in the perpendicular direction if the interaction were not perfectly coplanar. Earlier simulations show that the angle between the discs’ orientation and their orbit must be significant before the remnant takes on an elliptical morphology (Bournaud, Jog & Combes 2005), leaving room for disc thickening before disc destruction. We will explore the possible parameters of low-inclination mergers in a future work.

As angular momentum exchange strongly drives the evolution of the merging galaxies, it is interesting to follow the angular momentum exchange between all components present, including the dark matter. Fig. 8 clearly shows that the largest angular momentum exchanges occur during the violent merging epoch between 400 and 800 Myr. Afterwards, all momenta evolve more slowly. The main feature is the loss of all the initially positive orbital angular momentum in each component, which is then transferred almost exclusively to the dark matter, except for a tiny fraction transferred to the internal spin of the gas and stars. This exchange is seen in the total global momentum (black full curve) in each panel of Fig. 8. It is particularly intriguing to note that both dark haloes acquire a large prograde rotation, an effect even more marked for the halo of the prograde galaxy.

Our simulation agrees with the results of Puerari & Pfenniger (2001) who first showed that a coplanar major merger between two disc galaxies could limit the heating effect and create an NGC 4550 look-alike. In their simulation, they consider either a parabolic or a circular orbit, assuming that the relative energy of the two galaxies coming from infinity has already been absorbed by some outer matter. Both orbits avoid excessive heating, but only the parabolic orbit produces the spectacular counter-rotation observed in NGC 4550. However, their simulations are limited in how they investigate the gas; they include gas in either the prograde galaxy or the retrograde galaxy, but do not consider the case where gas

\caption{Velocity evolution during the simulation. For the same epochs as Fig. 6, the left-hand panel shows the stellar density (solid black line), mean line-of-sight velocity (black dashed line) and velocity dispersion (dot–dashed red line) profiles. The central panel shows the mean stellar velocity profile of the resulting system again (solid black line), as well as those of the prograde (solid red line) and retrograde (solid blue line) galaxies individually. The right-hand panel is as the central panel but for the gas velocities. All the profiles were extracted from a 4.5 kpc thick horizontal slice taken from the edge-on projection shown in Fig. 6. All boxes are 30 kpc wide.}
\end{figure}
Figure 8. Angular momentum evolution during the simulation. The top left panel shows the sum of all components, while the other three are split into the dark matter halo, the stars and the gas, as indicated above each panel. The wiggles in the total angular momentum line in the upper left box reflect noise in the simulation of the order of 2–3 per cent. The colour scheme is as for middle and right-hand panels of Fig. 7, i.e. red for the prograde galaxy and blue for the retrograde galaxy. The solid lines indicate the orbital angular momenta, while the dashed lines indicate the internal spin momenta. The angular momentum is in units of $2.3 \times 10^{11} \, M_\odot \, \text{kpc km s}^{-1}$; note that the scale is different in each plot.

is present in both galaxies as we have done. Of course, the final distribution of the gas within the merger remnant will depend on its initial distribution in the two progenitor galaxies.

Di Matteo et al. (2008) have also studied dynamical mechanisms to produce counter-rotating systems, through the merging of a non-rotating early-type galaxy with a gas-rich spiral. In these types of mergers, the orbital momentum is transferred to the rotation of the early-type galaxy and to the outer parts of the spiral, while the centre of the spiral (gas and stars) keeps its retrograde momentum. The counter-rotation is then spatially marked (centre versus the outer parts), which is a different pattern than that observed in NGC 4550, where gas and stars are counter-rotating at the same location. The nature, amount and extent of the observed counter-rotation can thus help to determine the merging history of the system.

4 STAR FORMATION

The CO detected in NGC 4550 indicates the potential for star formation, as stars originate in cold molecular gas. Using the Toomre density criterion, $Q$, with a conservatively cold velocity dispersion of $6 \, \text{km s}^{-1}$ and an epicyclic frequency measured from the rotation of the ionized gas (Sarzi et al. 2006), we calculate a threshold density ($Q = 1$) of $285 \, M_\odot \, \text{pc}^{-2}$. Determining a gas surface density for NGC 4550 from the CO data is difficult given the lack of resolution, but assuming a uniform-density, symmetric 5-arcsec-radius disc, we obtain a surface density of only $18.3 \, M_\odot \, \text{pc}^{-2}$ for the molecular gas, far below the threshold. Even decreasing the radius to 2 arcsec, about the minimum believable extent of the molecular gas, gives a surface density of only $115 \, M_\odot \, \text{pc}^{-2}$, still below the star formation threshold density. However, if the molecular gas is significantly more clumpy than a uniform density disc, then there may be isolated regions where the critical density is reached. We therefore do not immediately rule out the possibility of star formation in NGC 4550, instead looking for signs in other star formation tracers.

Far-infrared (FIR) emission is often used as a tracer of star formation, as young OB stars efficiently heat their surrounding dust. In late-type galaxies where the ultraviolet (UV) and visible radiation is dominated by young stars, the FIR emission is a very good tracer of star formation. Its use in earlier-type galaxies, however, is more disputable, as the radiation field of old hot stars should also contribute to the dust heating. Yet, the relations between other tracers of star formation such as H$\alpha$ (e.g. Kewley et al. 2002) and radio continuum (e.g. Gavazzi, Cocito & Vettolani 1986) hold puzzlingly constant with morphology (at least within spirals), indicating that it is dust proximate to star-forming regions which dominates the FIR emission. Converting the IRAS 60 and 100 $\mu$m fluxes into a star formation rate (SFR) following the prescription of Kewley et al. (2002), we derive a FIR-based SFR of $\approx 0.017 \, M_\odot \, \text{yr}^{-1}$ for NGC 4550.

As many early-type galaxies without star formation also emit in the FIR (an active galactic nucleus or infrared cirrus can also contribute), we do not want to rely on the FIR emission alone to ascertain ongoing star formation in NGC 4550. Instead, we look to the UV, where young stars are particularly bright. The first diagnostic we consider is the NUV-V colour. Using optical data from the MDM 1.3-m telescope (Falcón-Barroso et al. in preparation) and GALEX UV data (Jeong et al. in preparation), we have produced a plot of the NUV-V colour along the major axis of NGC 4550 (Fig. 9). NGC 4550 has a central NUV-V colour of around 5, becoming
bluer with increasing radius. While old stars can also emit in the UV, producing the UV-upturn phenomenon seen in old galaxies (e.g. Burstein et al. 1988, see O’Connell 1999 for a review), the bluest NUV-V colour this effect produces is $NUV-V = 5.2$ (Yi et al. 2005). Thus, the NUV-V colour in NGC 4550 is more likely from young stars. Furthermore, the decreasing gradient (bluer colour with increasing radius) is not seen in UV-upturn galaxies, reinforcing the idea that the NUV emission comes from young stars.

To investigate this possibility, we have used the method described in Jeong et al. (2007) to fit a two-stage star formation history to the UV-optical colours of NGC 4550. An old population is fixed at an age of 10 Gyr with a composite metallicity, while a younger component at solar metallicity is allowed to vary in age (0.001 Gyr < $t_{YC}$ < 10 Gyr) and mass fraction ($10^{-7} < f_{YC} < 1$). Fig. 10 shows the results of these fits, pixel by pixel. The central region appears to host a young stellar population (fitted age around 100 Myr), although the mass fraction is very low at only 0.01 per cent. To increase the signal-to-noise ratio and thus the reliability of our model fits, we computed integrated colours for the central region where the CO emission is detected, using an ellipse with a major axis of 5 arcsec, a minor axis of 3 arcsec and a position angle of 0°. The colours from this aperture give a best-fitting age of 280 Myr with $5.89 \times 10^7 M_\odot$ of young stars. The fit to the spectral energy distribution (SED) of this central region of NGC 4550 is shown in Fig. 11. As seen in the figure, NGC 4550 is slightly bluer in $NUV-V$ than the strong UV-upturn galaxy NGC 4552 and much bluer than the intermediate-age compact elliptical M32, indicating that young stars must be responsible for the blue $NUV-V$ colour of NGC 4550.

Absorption line strengths also give an indication of a young or intermediate-age population in NGC 4550. While absorption line strengths are not sensitive to the very youngest stars, they can easily reveal stellar populations 1 Gyr or older. The age-sensitive line strength $H_\beta$ (measured on the Lick/IDS system) is relatively high in NGC 4550, at a value of 1.99 Å integrated over an effective radius ($R_e$) and 2.14 Å integrated over $R_e/8$ (Kuntschner et al. 2006), reaching a value of 2.2 Å in the very centre (Maier et al., in preparation). Observations with the Multi-Pupil Fibre Spectrograph (MPFS) measured lower $H_\beta$ line strengths, however these were not corrected for the contamination from the H\beta emission line (Afanasiev & Sil’chenko 2002). These line strength values are hard to reproduce with only old (>5 Gyr) stars and more likely indicate a young or intermediate-age population, perhaps dating from the time of the merger. As with the UV, there is again an age–mass fraction degeneracy, with a smaller fraction of young stars producing an analogous effect to a larger fraction of intermediate-age stars.

Unfortunately, neither the UV nor the absorption line strengths can conclude anything about ongoing star formation in NGC 4550, while the FIR only gives an upper limit. To investigate ongoing star formation further, we look at optical emission line ratios and polyaromatic hydrocarbon (PAH) emission. Particularly low ratios of [O\ii] to $H_\beta$ emission lines (log([O\ii]/$H_\beta$) < -0.2) indicate current star formation (<20 Myr) as the source of ionization (Ho, Filippenko & Sargent 1997). Data from SAURON indicate that log([O\ii]/$H_\beta$) is between 0.15 and 0.5 for NGC 4550 (Sarzi et al. 2006). While gas could be star forming at these high values, it is more probable that shocks, post-asymptotic giant branch stars or an AGN are the dominant source of ionization (Sarzi et al. in preparation). The greater physical extent of the ionized gas compared to the molecular gas (see Fig. 4) also supports the idea that star formation is not the primary ionization source. Similarly, although the PAH emission detected in NGC 4550 (Bressan et al. 2006) is

**Figure 9.** $NUV$ and $V$ surface brightness profiles and $NUV-V$ colour along the major axis in NGC 4550. The vertical dashed line indicates the effective radius while the horizontal dashed line indicates the blue limit to the colours the UV-upturn phenomenon can produce, $NUV-V = 5.2$.

**Figure 10.** Left-hand panel: two-component fit map of the age of the young component (in Gyr). Right-hand panel: two-component fit map of the mass fraction of the young component. Note that the mass fraction is relevant to each individual pixel, thus a certain mass fraction in the central pixels represents a larger mass of young stars than the same mass fraction in outer pixels.
Molecular gas and star formation in NGC 4550

Figure 11. Integrated V, NUV and FUV fluxes for the central region of NGC 4550. The central region is defined by an ellipse of $5 \times 3$ arcsec$^2$, PA = $0^\circ$. The SEDs of the best-fitting young and old components are shown, along with the SED of the sum of these components. We have also shown the integrated colours of NGC 4552 (strong UV-upturn galaxy) and M32 (intermediate-aged compact elliptical) normalized in the V band for comparison. Inset: $\chi^2$ contours of the two-component stellar population fit to the central integrated colours of NGC 4550, showing the age–mass fraction degeneracy. The best fit is marked with an ‘x’.

suggestive of star formation, the PAH spectrum lacks the distinctive line ratios seen in star-forming regions. This different spectrum may just reflect a very low SFR (Galliano et al. 2008), but it may also indicate another source of PAH excitation altogether (Smith et al. 2007). Thus, with the available data, we cannot say more than that the SFR in NGC 4550 is less than about $0.02 M_\odot$ yr$^{-1}$, as indicated by the FIR emission.

At this rate, the amount of molecular gas we detect in NGC 4550 can fuel star formation for up to 350 Myr. The molecular gas is likely related to the young population (280 Myr) found in the UV, although whether the star formation has proceeded continuously or in a more episodic fashion since then is impossible to say. Depending on the interpretation of the line strengths, the star formation period may be of an even longer duration (extending back to more than 1 Gyr) or the moderately high line strengths may reflect a stellar population originating in the merger that formed NGC 4550.

5 CONCLUSIONS

We detect a very small amount ($1 \times 10^7 M_\odot$) of molecular gas in the centre of the counter-rotating red disc galaxy NGC 4550. The CO(1-0) emission is limited to the central 750 pc (10 arcsec) and is asymmetrically distributed, stronger at positive relative velocities north of the galaxy centre. The molecular gas co-rotates with the thick stellar disc and the ionized gas, counter-rotating with respect to the thin stellar disc.

Our simulation of the merger of two counter-rotating coplanar disc galaxies shows that the main features of NGC 4550 can naturally be explained with such a scenario. The interaction heats the prograde disc more than its retrograde companion and the gas component ends up aligned with the total angular momentum (dominated by the orbital angular momentum), and thus with the prograde disc. Thus, the gas is predicted to always rotate like the dynamically hotter disc, as observed in NGC 4550. As the gas accretion scenario does not provide a natural explanation for the corotation of the gas and thick disc, the merger scenario appears the more likely.

Both the UV and optical-line strength data indicate that NGC 4550 cannot be made up of a purely old stellar population. The best-fitting two-population model to the UV-optical photometry in the region with observed molecular gas gives a young population of 280 Myr and mass of $5.89 \times 10^7 M_\odot$. The optical H$\beta$ line strength value requires a population at least younger than 5 Gyr. Ongoing star formation in the observed molecular gas is possible if there are locally dense regions that exceed the critical density. The FIR emission gives an upper limit on the current SFR of $0.02 M_\odot$ yr$^{-1}$. This low SFR combined with the small amount of molecular gas present suggests that we are witnessing either a weak period in an extended bursty star formation episode or a more continuous very low level star formation episode that will last about another 350 Myr.

ACKNOWLEDGMENTS

The authors acknowledge receipt of a Daiwa Anglo-Japanese Foundation small grant and a Royal Society International Joint Project grant, 2007/R2-IJP, which facilitated this work. We would like to thank Philippe Salome for help with the reduction of the Plateau de Bure data. We are also grateful to the SAURON Team for providing SAURON data, including as yet unpublished MDM and GALEX images. LMY acknowledges support from grant NSF AST-0507432 and would like to thank the Oxford Astrophysics Department for its hospitality during sabbatical work. MB acknowledges support from NASA through GALEX Guest Investigator program GALEXGI04-0000-0109. This work was supported by grant No. R01-2006-000-10716-0 from the Basic Research Program of the Korea Science and Engineering Foundation to SKY.

This work is based on observations carried out with the IRAM Plateau de Bure Interferometer. IRAM is supported by INSU/CNRS (France), MPG (Germany) and IGN (Spain). Also based on observations carried out with the NASA GALEX. GALEX is operated for NASA by the California Institute of Technology under NASA contract NAS5-98034. The NASA/IPAC NED is operated by the Jet
